## Abstract

**Purpose.** Anterior tongue shape during /s/ production is often described as “tip-up” or apical, versus “tip-down” or laminal. Typically, this is determined by observing the shape of the anterior midline tongue. The purpose of this study was to identify methods of curvature calculation that quantify the observed shape differences and to examine whether the shape differences were affected by palate shape. Previous work shows that palate height has some effect (Grimm, et al., 2017).

**Method.** Four curvature-based measures were applied to a series of points selected along the tongue surface in midsagittal cine-MR images during speech. The measures were minimal curvature, averaged largest curvature (ALC), normalized ALC, and interpolated normalized ALC. These measures were compared to visual judgments of apical and laminal /s/. Anterior palate shape was measured from dental casts.

**Results.** The apical /s/ contained a flat or concave region in the anterior tongue, while the laminal /s/ had a convex shape along the entire tongue. Thus, the laminal shape was less complex than the apical. The last two metrics, based on averages of multiple

1  
2  
3  
4 normalized curvatures, captured this complexity difference. Subjects with a more  
5  
6  
7 steeply sloped anterior palate tended to use laminal /s/.  
8  
9

10 **Conclusion.** The tongue shape for the two /s/-types was best defined by complexity of  
11  
12  
13  
14 the shape, rather than local anterior shape. Statistical quantities that measured  
15  
16  
17 curvature in multiple locations, and normalized across subjects, were best at  
18  
19  
20  
21 distinguishing the two /s/ shapes. Interpolating additional points between the manually  
22  
23  
24 selected ones did not improve the method.

## INTRODUCTION

The primary goal of this study is to create a simple, clinically useful method, based on curvature, to objectively quantify midsagittal tongue shape during apical and laminal /s/.

The midsagittal tongue was chosen as the measurement site, because the midline vocal tract shape is the best single representative of the 3D vocal tract contour, and because 2D midline data sets are available to researchers more often than 3D data sets. The anterior tongue was measured because it executes the linguo-alveolar constriction used in /s/. Several curvature methods were tested to determine the one that best captures the shape features used by human observers (raters) when categorizing /s/-type from MRI images. In addition, we considered whether midline palate shape, that is, anterior slope and convexity, affect anterior tongue shape and choice of /s/-type.

### **Apical and Laminal /s/**

The tongue shape during /s/ is a funnel, wider at back, which focuses and narrows the airstream into the alveolar constriction and onto the anterior teeth (cf. Stone and

1  
2  
3  
4 Lundberg, 1996), There are two types of /s/ production, apical and laminal (see Dart,  
5  
6  
7 1991). For both types, the sides of the tongue contact the lateral palate and inner  
8  
9  
10 surface of the teeth, producing a tongue groove along the vocal tract midline to direct  
11  
12  
13 the air stream toward the incisors. The key difference between the two productions  
14  
15  
16 occurs in the anterior tongue. The apical /s/ creates the alveolar constriction with the  
17  
18 tongue tip, while the laminal /s/ uses the tongue blade (Dart, 1991) (see Figure 1).  
19  
20  
21

22  
23  
24 Apical and laminal tongue motions are usually categorized subjectively by direct  
25  
26  
27 observation of the tongue shape in a midsagittal tongue image (cf. Dart 1998).  
28  
29  
30

31  
32  
33 The use of apical or laminal /s/-type, has been thought historically to be idiosyncratic  
34  
35  
36 and somewhat random across speakers. There is no audible acoustic or perceptual  
37  
38  
39 difference between the two /s/-types (Stoner, Gately and Rivers, 1987, Dart, 1991,  
40  
41  
42 1998). In addition, there is little evidence of languages preferring one type of /s/. Dart  
43  
44  
45 (1998) studied /s/-type in 20 English and 21 French speakers based on palatograms  
46  
47  
48 and linguagrams. She found 58% of American English speakers and 68% of French  
49  
50  
51 speakers used laminal /s/. Icht and Ben David (2017) used self-report to categorize /s/-  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 type in 100 Hebrew speakers. They found about 60% used laminal /s/ with no effect of  
4  
5  
6  
7 age, gender, or country of birth. Understanding the differences between /s/-types is  
8  
9  
10 useful when training speakers to produce a correct /s/, however. It is easier for a patient  
11  
12  
13  
14 to correct their /s/ in the direction of their natural preference, apical or laminal.

### 21 **Quantification of Tongue Surface Shape**

22  
23  
24  
25  
26  
27  
28 Tongue shape differences due to phoneme categories have been quantified from  
29  
30  
31 ultrasound images of the midsagittal tongue. Curvature signatures and polynomial  
32  
33  
34  
35 functions quantify global tongue shapes in isolation, because ultrasound images do not  
36  
37  
38 capture other vocal tract features (Morrish et al., 1984, 1985). A combination of  
39  
40  
41  
42 curvature signatures and polynomial functions comprise the Curvature Index (CI) (Stolar  
43  
44  
45 and Gick, 2013). The CI method applies a seventh order fit to a tongue surface contour,  
46  
47  
48  
49 and then integrates the curvature of every point in the fit to create a single quantity  
50  
51  
52 representing tongue shape complexity. That study found that the /s/ and /z/ midsagittal  
53  
54  
55  
56 tongue shapes are among the lowest in shape complexity for English phonemes; the  
57  
58  
59  
60

1  
2  
3 study did not examine apical and laminal contrasts. In another study, Dawson, et al.,  
4  
5  
6  
7 (2016) compared a modified curvature index (MCI) to a Procrustes analysis (translation,  
8  
9  
10 rotation, scaling), and Fourier analysis (DFT) of ultrasound tongue shapes. The three  
11  
12  
13 methods were all successful at labeling tongue shape complexity, with DFT being the  
14  
15  
16  
17 best. Principal components analysis (PCA) also provided good success in eliminating  
18  
19  
20 noise effects and facilitate quantification of tongue shapes from ultrasound images (cf.  
21  
22  
23 Harshman, Ladefoged and Goldstein, 1977, Slud et al., 2002, Hoole and Pouplier,  
24  
25  
26  
27  
28 2017).

29  
30  
31  
32  
33 The present study is interested in subtle, local tongue shape differences between /s/-  
34  
35  
36 types, not the global effects of phonemic categories. The study uses MRI because it  
37  
38  
39  
40 does a good job at imaging the anterior tongue, where the /s/-constriction and the  
41  
42  
43 apical/laminal differences are located. MRI has had more success in distinguishing  
44  
45  
46  
47 apical and laminal /s/ than ultrasound. Narayanan et al., (1995) used MRI to study /s/-  
48  
49  
50 type, and found that apical fricatives showed deeper grooving behind the constriction  
51  
52  
53  
54 than laminal ones. Our study aims to develop a quantity that captures subtle and local  
55  
56  
57  
58  
59  
60

1  
2  
3 differences between laminal and apical /s/, which may include tongue shape complexity,  
4  
5  
6  
7 and which should be applicable to distinguishing other sounds that differ in only one  
8  
9  
10 region of the tongue.  
11  
12  
13  
14  
15

### 16 **Palate Effects.**

17  
18  
19  
20

21 Our previous studies of /s/-type used MRI and dental casts to identify effects of palate  
22  
23  
24 height on /s/-type. Stone et al. (2013) and Grimm et al. (2017) compared palate vault  
25  
26  
27 height to /s/-type for single words in glossectomy patients and healthy controls. They  
28  
29  
30 showed that controls with low palates tended to use apical /s/, while those with high  
31  
32  
33 palates tended to use laminal /s/. It is possible that a low palate does not provide  
34  
35  
36 sufficient clearance for the tongue body elevation observed in laminal /s/. Alternatively,  
37  
38  
39 palate height could change the aerodynamics of the airflow into the constriction, thus  
40  
41  
42  
43  
44  
45  
46 affecting the nature of /s/ production.  
47  
48  
49  
50

51 Studies of palate doming offer another perspective on the effects of the hard palate on  
52  
53  
54 tongue behavior. Palate doming combines palate height and width, often by fitting a  
55  
56  
57  
58  
59  
60

1  
2  
3 quadratic function to a coronal section of the palate. Three studies examined the effect  
4  
5  
6  
7 of palate doming on /s/ variability. Brunner et al., (2009) examined variability in EPG  
8  
9  
10 contact patterns and found that speakers with low domed palates used little articulatory  
11  
12  
13 variability in target EPG pattern for /s/, whereas some with high domes had large  
14  
15  
16  
17 variability. Yunusova et al., (2012) used EMA to measure variability in tongue height  
18  
19  
20 during consonants. They also found that subjects with low domed palates had less  
21  
22  
23 variability than those with high domed palates. Bakst (2016), in a PCA analysis of  
24  
25  
26  
27 ultrasound images, also found that subjects with low-domed palates had less  
28  
29  
30 articulatory variability in /s/ than those with high-domed palates. These studies did  
31  
32  
33  
34 statistically analyze apical vs laminal effects. The present study will consider only  
35  
36  
37  
38 midline palate shape, that is, how the slope and convexity of the anterior midline palate  
39  
40  
41  
42 influence the shape of the anterior tongue and the choice of apical versus laminal /s/.  
43

## 50 **Magnetic Resonance Imaging.**

51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 Magnetic Resonance Imaging (MRI) uses a strong magnetic field and radio frequency  
5  
6  
7 excitations to image various properties of the hydrogen atoms in tissue (cf. Brown, et  
8  
9  
10 al., 2014). Soft tissue has a high water content, so MRI is a highly useful and minimally  
11  
12  
13  
14 invasive technique to study soft tissue anatomy (cf. Stone et al., 2018). Cine-MRI (as in  
15  
16  
17  
18 cinema) can be used to capture the dynamic movements of subjects' tongues while  
19  
20  
21 performing speech tasks, enabling morphological characterization at the instant the /s/  
22  
23  
24 sound is generated. Cine-MRI captures image information over several minutes while  
25  
26  
27  
28 the subject repeats the task, and this information is pieced together to create a movie  
29  
30  
31 that represents a single execution of the task. Cine-MRI yields lower spatial resolution  
32  
33  
34  
35 than that of anatomical MRI, which is captured while the subject lies still for several  
36  
37  
38  
39 minutes. However, movies generated by cine-MRI have sufficient spatial resolution to  
40  
41  
42 allow clear visualization and measurement of the midline tongue surface (see Figure 1).  
43

## Curvature.

Most studies categorize /s/ production using visual inspection of data. Human raters attempt to distinguish between the two /s/-types by observing the midsagittal tongue profile (see Figure 1). The present study aimed to validate this type of categorization with a more objective measure of /s/-type, namely the curvature of the anterior midline tongue. Human ratings of /s/-type were used to test four curvature-based metrics that represent local and global tongue shape properties.

The curvature value,  $\kappa$ , represents the degree of deviation from a straight line at a point within a series of points (Casey, 1996). Here, the local curvature can be positive (i.e., arched or convex), zero (i.e., flat), or negative (i.e., depressed or concave). The midsagittal tongue profile in its entirety is naturally arched, or convex, at rest reflecting the curve of the vocal tract. Elevation of the tongue tip will reduce that convexity locally, more than elevation of the blade. Therefore, this study expected laminal /s/ to have a convex anterior tongue profile, because the blade is elevated by the body towards the alveolar ridge. For apical /s/, the anterior tongue profile was expected to be flatter or

1  
2  
3 even concave, because the tongue tip is elevated to a greater extent than the tongue  
4  
5  
6  
7 body.

14  
15  
16  
17 Figure 1 about here  
18

19  
20  
21 -----  
22

23  
24 Two hypotheses were proposed. First, curvatures for apical /s/ were expected to be  
25  
26  
27  
28 higher-dimensional than those for laminal /s/ due to a local flatness or concavity in the  
29  
30  
31 anterior tongue for apical /s/. Second, we expected that steeper palate slopes and a  
32  
33  
34 more protruded (convex) alveolar ridge region, would result in apical tongue shapes,  
35  
36  
37  
38 with a less high tongue body, to properly funnel the air into the constriction.

## 47 MATERIALS AND METHODS

### 48 49 50 51 Subjects

52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Participants for this study were twenty healthy, native speakers of American English,  
4  
5  
6  
7 who spoke with a Maryland regional accent. They were chosen from a larger database  
8  
9  
10 containing MRI and dental data and many have been used in previous studies, such as  
11  
12  
13 Stone, et al., (2013) and Grimm, et al., (2017). The subjects had normal hearing test  
14  
15  
16 results, including acuity, word recognition tests, and speech reception thresholds. The  
17  
18  
19 subjects had an average age of 35.8 years (SD=12) and included 9 males and 11  
20  
21  
22  
23  
24 females (n=20).  
25  
26  
27  
28

### 29 **Speech task**

30  
31  
32  
33 The speech task was /əsuk/ (“a souk”). This task was chosen for several reasons. First,  
34  
35  
36 it begins with a fairly neutral tongue position (schwa), and after the forward movement  
37  
38  
39 into /s/ the tongue motion is in a straightforward backward/upward direction. Second,  
40  
41  
42  
43 the high vowel minimizes jaw motion, maximizing the deformation of the tongue when  
44  
45  
46  
47 creating the sounds. Finally, the cine image acquisition was limited to 1 second to allow  
48  
49  
50  
51 comparison between these data and tagged data collected in the same session (not  
52  
53  
54 used in this study). For these subjects there was a distribution of /s/-types, with 12  
55  
56  
57  
58  
59  
60

1  
2  
3 apical and 8 laminal speakers (see Figure 2). Categorization of apical or laminal /s/ for  
4  
5  
6  
7 each subject was done independently by a speech scientist and two dentists trained by  
8  
9  
10 the speech scientist. The time-frame in which the tongue-palate constriction first  
11  
12  
13  
14 appeared for /s/ was chosen for measurement. The three raters used visual inspection  
15  
16  
17  
18 criteria consistent with Dart (1991, p. 12), who used the terms to refer to the part of the  
19  
20  
21 tongue used to make the constriction. Apical refers to the tip, and laminal to the blade.  
22  
23  
24 Disagreement by one rater was addressed by consultation among all three.  
25

## 41 Data Collection and Measurements

### 44 Cine-MRI.

45  
46  
47  
48 MRI data were acquired on a 3 Tesla Tim Trio scanner (Siemens Healthcare, Erlangen,  
49  
50  
51  
52 Germany), with a 12-channel head coil and a 4-channel neck coil. Cine MRI was  
53  
54  
55  
56 acquired using a segmented gradient echo sequence at an in-plane resolution of 1.875  
57  
58  
59  
60

1  
2  
3 mm/pixel, field of view (FOV) of 240 mm×240 mm slice, thickness of 6 mm, TE of  
4  
5  
6  
7 1.33 ms, and TR of 2 seconds. Five speech repetitions were used to complete data  
8  
9  
10 acquisition for each single slice including 26 time frames of 38 ms each. Cine-MRI  
11  
12  
13  
14 creates a single movie by ensemble summation of multiple repetitions of the speech  
15  
16  
17 task. Each time frame (1–26) is averaged with the same time frame from all five  
18  
19  
20 repetitions to boost signal strength because the signal emitted by the hydrogen protons  
21  
22  
23 in the short time frame is quite weak. The cine-MRI recordings were made during a 1 s  
24  
25  
26 recording period within a 2 s repeat cycle. Data were collected at multiple slices and in  
27  
28  
29 three orientations (sagittal, coronal, and axial). The mid-sagittal slice was identified  
30  
31  
32 based on all three datasets, and used for the tongue analysis in this study. Subjects  
33  
34  
35 were trained to speak the words to a 4-beat metronome to increase the precision of  
36  
37  
38 repetitions, using the methods of Masaki et al., (1999).  
39  
40  
41  
42  
43  
44

45 High resolution MRI volumes for each subject were collected in the same session as the  
46  
47  
48 cine-MRI data and in the same orientation, so that the two data sets could be overlaid  
49  
50  
51 (cf. Stone, et al., 2013). These volumes were used to identify the location of the anterior  
52  
53  
54 edge (alveolar) of the first molar tooth roots, which along with the mid-palate point at the  
55  
56  
57  
58  
59  
60

1  
2  
3 same location, formed a plane perpendicular to the occlusal plane. This plane served as  
4  
5  
6  
7 a landmark for placing the 5th midsagittal tongue surface point during the /s/.  
8  
9

### 14 15 **Dental cast.** 16

17  
18  
19 Dental casts were available for all subjects collected from alginate impressions and  
20  
21  
22 poured in dental stone. Subjects were not included if they were missing first molars,  
23  
24  
25 had a significant palatal torus, or if the cast had major imperfections that made palatal  
26  
27  
28 measurements inaccurate. The acceptable casts were scanned using a 3D optical  
29  
30  
31 scanner (Ortho Insight 3D Scanner, Motion View Software, 2016). Three landmarks  
32  
33  
34 were measured on both the stone and digital dental casts (see Figure 3a). These three  
35  
36  
37 material points and the occlusal plane were used to calculate the convexity angle and  
38  
39  
40 the slope of the anterior palate. The stone casts were measured by hand using dial  
41  
42  
43 calipers. The digital casts were measured using MeshLab V1.3.3 (Cignoni et al., 2008).  
44  
45  
46  
47  
48  
49  
50 Those digital and stone cast values that did not agree were remeasured. Once the  
51  
52  
53 digital points were accurately identified, the 3-dimensional coordinates were exported to  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 an Excel spreadsheet (Microsoft, Seattle, USA) file for analysis. The two palate angles  
4  
5  
6  
7 were calculated as follows:  
8  
9  
10  
11  
12  
13  
14

15  
16 **1. Convexity Angle (CA):** This angle quantifies the prominence of the alveolar  
17  
18  
19 ridge of the hard palate. The CA is formed by an angle formed by points 1, 2, 3 in  
20  
21  
22 Figure 3, a and b. These points represent the central incisor interdental papilla  
23  
24  
25  
26 (point 1), the base of the incisive papilla (point 2) , and the palate high-point  
27  
28  
29 adjacent to the first molars (point 3), shown as black dotted lines (Figure 3b).  
30  
31  
32  
33 The incisive papilla is a small oval protruberance that sits on the incisive foramen  
34  
35  
36 directly behind the central incisor teeth. As it is a protuberance, the CA is always  
37  
38  
39 slightly convex. The subjects were divided into two groups based on the range of  
40  
41  
42  
43 their convexity angles, which was 147° to 177°. Higher numbers indicate flatter,  
44  
45  
46  
47 less convex shapes, because 180° is flat (colinear points). Low convexity angles  
48  
49  
50  
51 were defined as  $\leq 173^\circ$ , which was the median value.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 **2. Anterior Angle (AA):** The AA is at point 0, and is formed by the projection of a  
5  
6  
7 line (dashed green) drawn between the base of the incisive papilla (point 2) and  
8  
9  
10 the interdental papilla (point 1) at the intersection with the occlusal plane (point  
11  
12  
13  
14 0). The perpendicular from the occlusal plane to the base of the incisive papilla  
15  
16  
17 (Figure 3b, vertical green line) completes the triangle. The anterior angle  
18  
19  
20 represents the slope of the anterior midline palate. Subjects were sorted into two  
21  
22  
23  
24 AA Groups, where low angles were  $\leq 37.0^\circ$ , which was the median angle of our  
25  
26  
27  
28 larger database.

53  
54  
55  
56  
57  
58  
59  
60

**Tongue profile point sequence:** The midline tongue profile was identified in the  
time-frame identified as the maximum constriction for /s/. Eight roughly equidistant

1  
2  
3  
4 tissue points were selected as xy coordinates. Five were between the tongue tip and the  
5  
6  
7 first molar, and three were posterior to the first molar. In order to normalize points  
8  
9  
10 across subjects the following method was used. Point 1 was the most anterior point on  
11  
12  
13 the upper profile of the tongue. Point 5 was selected at the plane cut by the M1 roots  
14  
15  
16 onto the profile of the midsagittal tongue (see Figure 3c). To make this projection, a  
17  
18  
19 vertical plane was defined at M1 by selecting 3 points—one at each M1 alveolus and a  
20  
21  
22 third point at the midpoint of the palate at the M1 alveolus. These 3 points defined a  
23  
24  
25 plane perpendicular to the occlusal plane, which cuts through the tongue coronally at  
26  
27  
28 the first molar (Grimm et al., 2017). Points 2, 3, and 4 were selected manually to be  
29  
30  
31 equidistant visually between points 1 and 5. The first 5 points covered the region of the  
32  
33  
34 tongue tip and blade. Since human observers may use more than just the tip and blade  
35  
36  
37 in making their decision, points 6–8 were selected posterior to point 5 using the same  
38  
39  
40 manual selection of spacing as the first 5 points. This allowed a larger shape region to  
41  
42  
43  
44  
45  
46  
47  
48  
49 be considered objectively.

2  
3  
4 ***Basic Curvature calculation:*** The resulting sequence of 8 points was considered  
5  
6  
7 to be part of a curve on which  $\kappa$  (curvature) was calculated by fitting a circle to every 3  
8  
9  
10 consecutive points ( $\kappa$  was not defined at the endpoints). We approximated *local* values  
11  
12  
13 of  $\kappa$  by fitting a circle of radius  $r$  passing through 3 adjacent Cartesian points in the  
14  
15  
16 sequence described above (Cassey, 1996). For 3 such points (say,  $p_1$ ,  $p_2$ , and  $p_3$ ),  $\kappa =$   
17  
18  
19  $r^{-1}$  at the center point can be extracted from  
20  
21  
22

$$r = \frac{1}{2} \frac{\|v_{12}\| \|v_{13}\| \|v_{32}\|}{\|v_{axis}\|}, \quad (1)$$

23  
24  
25  
26  
27  
28  
29 where  $v_{12}$ ,  $v_{13}$ , and  $v_{23}$  are vectors between the points, and  $v_{axis} = v_{12} \times v_{32}$  is normal  
30  
31  
32 to the plane in which the circle is defined. Curvature calculations were implemented in a  
33  
34  
35 script written in MATLAB v2015a (Natick, MA, USA). Curvature values were assigned a  
36  
37  
38 sign to represent whether the local shape acted with or against the global convexity of  
39  
40  
41 all points along the tongue profile. Figure 4 shows the global curvature represented as a  
42  
43  
44 dotted circle with radius  $R$ , which has been fitted to the points in the 8-point sequence  
45  
46  
47 using least squares (Gander, 1994). The direction of the global convexity is represented  
48  
49  
50  
51  
52  
53  
54 by the vector from each point in the sequence towards the center of the circle (C)  
55  
56  
57  
58  
59  
60

1  
2  
3 associated with  $R$ . Likewise, the local curve shape is represented by the vector from

4  
5  
6 each point to the center of the local circle ( $c$ ) associated with  $r$  (solid blue or solid red).

7  
8  
9 Thus,  $\kappa$  was negative if the angle between the vectors ( $C,P,c$ ) was greater than  $90^\circ$

10  
11  
12 (Figure 4, point 3), and positive if the angle was less than  $90^\circ$  (point 7).

30  
31 ***Profile shape classification:*** As a reference, apical and laminal /s/ were identified

32  
33  
34 from the images by visual inspection as described above. For quantification, four data-

35  
36  
37 driven approaches were also used to classify the shapes based on the 8 point

38  
39  
40 sequence. Because the data points are coarse, several mm apart, some of the methods

41  
42  
43 below include normalization of subject size as well as refinement by adding more points.

44  
45  
46  
47  
48

56  
57  
58  
59  
60

1  
2  
3  
4 **1. Minimum Curvature (MC).** This method uses the minimum local curvature  
5  
6  
7 value among the measured points, be it a small convex or a large concave curve.  
8  
9  
10 Negative values of  $\kappa$  represent a local concavity in the overall curvature. Using  
11  
12  
13 this approach, the lowest curvature values during /s/ typically occurred at points  
14  
15  
16  
17 3, 4 or 5, so the lowest of these three values was selected to represent the  
18  
19  
20 anterior tongue shape for the /s/ of that subject. (The concept is illustrated in  
21  
22  
23 Figure 5, row 1.) This is the only one of the methods that used the sign of the  
24  
25  
26  
27 curvature and is fairly intuitive in reflecting concave versus convex minima.  
28  
29  
30

31  
32 **2. Averaged Largest Curvatures (ALC).** The ALC method consists of classifying  
33  
34  
35 profile shapes based on the largest curvature values (or smallest  $r$  circles), to  
36  
37  
38 capture deviations from the smooth arc formed by the anterior tongue profile (as  
39  
40  
41  
42 shown in Figure 5, row 2). It is not sign sensitive. The two largest curvature  
43  
44  
45  
46 values were averaged together because the addition of a second anatomical  
47  
48  
49 region increases sensitivity to the complexity of the profile curve. The largest  
50  
51  
52  
53 curvature values are examined irrespective of sign, and thus do not contain zero  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 values. This prevents flat surfaces of the tongue from dominating the  
4  
5  
6  
7 classification results. Flat surface regions can occur locally in both apical and  
8  
9  
10  
11 laminal /s/ shapes.

12  
13  
14  
15 **3. Normalized ALC (NALC).** To account for size differences between subjects,  
16  
17  
18 the ALC method was normalized using the global curvature. The ALC was  
19  
20  
21 inverted to approximate a radius, which was then divided by the size  
22  
23  
24  
25 normalization factor,  $R$  (see Figure 5, row 3). As with ALC, this approach  
26  
27  
28 captures the complexity of the curve, and includes normalization as well as  
29  
30  
31  
32 averaging.

33  
34  
35  
36 **4. NALC with Interpolation (NALCi).** This method consisted of recalculating NALC  
37  
38  
39 after refining the point sequence by interpolating 10 additional points between  
40  
41  
42  
43 each original point via a cubic spline. This method determines whether point  
44  
45  
46  
47 distance is important when calculating curvature. The use of 78 points instead of  
48  
49  
50  
51 8 enables a better approximation of local curvatures. The length scale differs for  
52  
53  
54 each subject based on the size and spacing of their teeth; tissue point 5 is  
55  
56  
57  
58  
59  
60

1  
2  
3 located at the first molar. To maintain sensitivity to the length scale, the top 20  
4  
5  
6  
7 local curvatures or 1/4<sup>th</sup> of the curvature measurements were averaged instead  
8  
9  
10 of the top 2 as in NALC.  
11  
12

24  
25  
26  
27

28 The presented approaches are intended to balance efficacy and conceptual  
29  
30  
31 accessibility based on our experience. However, the list of methods described above is  
32  
33  
34 by no means exhaustive, and there are multiple plausible shape classification schemes.  
35  
36  
37  
38 For instance, it is possible to approximate the properties of a continuous curve  
39  
40  
41 (including rotation, axial torsion, and cumulative curvature through a line integral) as has  
42  
43  
44  
45 been demonstrated to classify shape differences in the spine (Donzelli, 2015), or to  
46  
47  
48 measure diversity of curvature via the standard deviation of local curvature values.  
49  
50  
51  
52

### 53 **Statistical Analyses**

2  
3  
4  
5  
6  
7 Mypstat 12 (Systat Software, San Jose, CA) was used to calculate statistics on these  
8  
9  
10 data. Because of the small amount of data, non-parametric statistics were used. First, a  
11  
12  
13 Spearman's Rho correlation (Myers and Well, 2003) was performed between AA and  
14  
15  
16 CA, to determine whether the two palate measurements were independent of each  
17  
18  
19 other (see Figure 6). They were found to be uncorrelated ( $\rho=0.005$ ). A rho of 2.11  
20  
21  
22 was needed for significance at  $p=0.05$  given the number of subjects in the study.  
23  
24  
25  
26  
27 Therefore, the two palate angles were treated independently in subsequent analyses.

## RESULTS

We hypothesized that the curvature-based metrics would classify the anterior tongue profile into categories of apical and laminal /s/ consistent with the subjective classification of three raters. To test this, the four curvature quantities, MC, ALC, NALC, and NALC<sub>i</sub>, were compared to the apical and laminal subjectively rated groups.

The metric classification results appear in Table 1 and are visualized in Figures 7 and 8.

The MC method did not show a significant difference between the apical and laminal shape categories ( $U = 26$ ,  $p = 0.09$ ) (see Figures 7 and 8). However, the ALC analysis without normalization also did not show a significant difference between the apical and laminal shape categories ( $U = 55$ ,  $p = 0.589$ ) (Figures 7 and 8).

The third measure, the NALC, resulted in a statistically significant differentiation between /s/ types ( $U = 16$ ,  $p = 0.028$ ). The NALC, which measures the ratio between the averaged largest curvatures and the global curvature, found that the laminal curvatures were more similar to the global curvatures than were the apical ones, that is,

1  
2  
3 the ratio was closer to 1. The laminal profiles had a median ratio of  $0.368 \pm 0.14$  and the  
4  
5  
6  
7 apical median was  $0.225 \pm 0.10$  (Figures 7 and 8). This means that the apical tongue  
8  
9  
10 had a less convex shape, often containing an anterior local concavity. Thus, this metric  
11  
12  
13  
14 captured somewhat more complexity in the apical than the laminal /s/.  
15  
16  
17

18 The final metric, NALCi, was also statistically different between groups ( $U=15$ ,  $p=0.028$ ).  
19

20  
21 The laminal profiles had a median value of  $0.260 \pm 0.10$  for, and the apical profile  
22  
23  
24  
25 shapes averaged  $0.158 \pm 0.07$  (see Figures 7 and 8). A correlation showed that NALC  
26  
27  
28 and NALCi were highly correlated ( $R=0.99$ ).

-----

1  
2  
3  
4 In addition to the /s/-type effect, this study examined the effect of palate shape and  
5  
6  
7 slope on curvature. Mann Whitney U tests found that palate convexity angle (CA) had  
8  
9  
10 no significant effect on curvature. The anterior angle (AA), however, did have a  
11  
12  
13 significant effect on tongue shape for NALC (U = 16, p = 0.019). Less steep anterior  
14  
15  
16  
17 palate slopes were more likely to produce an apical /s/. AA was close to significant,  
18  
19  
20  
21 with identical U and p values, for MC (U = 21, p = 0.052), and NALCi (U= 21, p=0.052).

## 32 DISCUSSION

### 33 34 35 36 37 38 39 **Apical-Laminal Effect on Curvature**

40  
41  
42  
43 The main goal of this study was to use curvature to capture quantitatively apical and  
44  
45  
46  
47 laminal /s/ shapes in the midsagittal tongue. Within even a single tongue profile there  
48  
49  
50  
51 is variability in curvature between the tip and the region beyond the first molar, as  
52  
53  
54  
55 measured in this study. In addition, vocal tract size differs across subjects, so scaling  
56  
57  
58  
59  
60

1  
2  
3 becomes an issue in quantification of shape. Visual inspection suggested that a laminal  
4  
5  
6  
7 /s/ was associated with a convex-to-flat tongue profile shape, while apical /s/ was  
8  
9  
10 associated with a flat-to-concave shape. Only the MC used signs when calculating  
11  
12  
13 curvature; the other three methods examined only curvature magnitude. Results  
14  
15  
16  
17 showed that using the normalized curvature quantities, NALC and NALC<sub>i</sub>, the subjective  
18  
19  
20 categories of apical and laminal /s/ predicted the shape of the anterior tongue very well  
21  
22  
23 (Figure 5, Table 1). The apical /s/ shape was slightly more complex than the laminal /s/,  
24  
25  
26  
27 with more zero crossings. Every time the curvature value passes through zero and  
28  
29  
30 switches sign, an inflection point occurs. More inflection points create more curvature  
31  
32  
33 minima. If the curvatures of the apical and laminal tongues had been mirror images, this  
34  
35  
36 method would not work; however, they were not. Thus, one outcome of this study was  
37  
38  
39  
40  
41 the observation that apical tongue contours have more shape complexity than laminal  
42  
43  
44  
45 ones.

## Metric Representation of Tongue Curvature

The second goal of this study was to optimize the curvature metric used to represent the midsagittal tongue profile. The simplest metric was the MC value as it identified the local tongue tip shape. However, an MC value near zero occurred in 1/2 of the subjects, and in both apical and laminal /s/ shapes (Figure 6). A value of zero arises when points are colinear, which can be a feature of the profile or from the digital nature of the images in cases where three consecutive points lay in the same (or close to the same) voxel row, resulting in a radius of curvature approaching infinity. For these subjects especially, it was clear that a larger region of the tongue needed to be used in quantifying its shape. The second metric, ALC, indicated that the radius of the smallest circles (largest local curvature) in the laminal /s/ profiles could be close in magnitude to the circle encompassing all points in the sequence (Figures 4 and 5). This was generally not the case for the shape of apical /s/ profiles, because the local circle fits were generally smaller than the global circle fit. However, this metric also failed to distinguish the shape categories. The third metric, NALC, included a normalization

1  
2  
3 factor (the global radius of curvature), which prevented tongue size differences from  
4  
5  
6  
7 affecting curvature values. Cases such as that shown in Figure 5 also suggest that  
8  
9  
10 apical profiles may have a larger radius of global curvature; thus, the numerator would  
11  
12  
13  
14 decrease while the denominator increases, magnifying the sensitivity of the metric. The  
15  
16  
17 NALC clearly distinguished between the two groups of tongue shapes in a manner  
18  
19  
20 consistent with the raters' categorizations. The similarity of results between the NALC  
21  
22  
23 and the fourth metric,  $NALC_i$ , indicated that the addition of interpolated points was less  
24  
25  
26  
27 important than normalizing the length scale used in the analysis (Figures 9, 10). Thus,  
28  
29  
30  
31 the automated, data-driven metrics showed that the human /s/ shape categories  
32  
33  
34  
35 appeared to follow curvature differences in the anterior tongue, in which apical /s/ had a  
36  
37  
38 more complex shape with a local flat or convex region.  
39  
40  
41

42  
43 It can be observed that subject 18 (S-18) was unusual. In Figure 6, S-18 was the outlier  
44  
45  
46 who had the least upwardly sloped and the most convexly shaped palate of all the  
47  
48  
49 subjects. S-18 also was physically a large person, with a large oral cavity and tongue.  
50  
51  
52  
53 Although S-18 was judged to have a laminal tongue shape, (Figure 2, subj 18), the tip  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 region was very flat, and not inconsistent with the apical shapes. The MC and ALC  
4  
5  
6  
7 methods put 18 in the middle reflecting the ambiguous shape. By dividing the largest  
8  
9  
10 curvatures by the global curvature, the NALC and NALCi eliminated the effects of the  
11  
12  
13 large tongue size by using a ratio, but that also removed the shape ambiguity in the  
14  
15  
16  
17 quantity. Instead, the large normalized circles used to comprise NALC and NALCi  
18  
19  
20 placed S-18 numerically in the apical region.  
21  
22  
23  
24  
25  
26  
27

### 28 **Palate Effects on Curvature.**

29  
30  
31  
32 This paper hypothesized that anterior palate shape might affect anterior tongue profile  
33  
34  
35 shape. The effect of CA on tongue shape was non-significant for all four metrics.  
36  
37  
38

39 However, the AA had a significant effect on NALC ( $p = 0.019$ ), and approached  
40  
41  
42 significance for MC ( $p = 0.052$ ) and NALCi ( $p = 0.052$ ). Flatter anterior palate slopes  
43  
44  
45  
46 were more likely to produce an apical /s/ and steeper ones led to laminal /s/. This was  
47  
48  
49 of interest as our previous research (Grimm et al., 2017) showed that palate height  
50  
51  
52  
53 affected the /s/-type categorization made by human raters. These two results are  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 consistent, because even though palate height does not correlate with AA, there is a  
4  
5  
6  
7 tendency for a steep AA to accompany a higher palate (Grimm, et al., 2017).  
8  
9  
10  
11  
12  
13  
14

## 15 CONCLUSIONS

16  
17  
18  
19  
20 This study found objective curvature measures of the midsagittal tongue, when scaled  
21  
22  
23 across subjects, supported the classical, visually-determined categories of apical and  
24  
25  
26 laminal /s/. More convex tongue shapes were associated with the laminal /s/ and  
27  
28  
29 occurred with steeper palate slopes. The flatter anterior palates, associated with the  
30  
31  
32 apical /s/, sometimes produced concave regions in the anterior tongue, and  
33  
34  
35 occasionally more complex profile shapes (more zero crossings). It is tempting to think  
36  
37  
38 that differences between these two /s/-types is entirely due to morphology of the palate.  
39  
40  
41  
42  
43 However, glossectomy patients tend to use laminal /s/ irrespective of palate features,  
44  
45  
46  
47 due to difficulty controlling the tongue tip (Grimm et al., 2017). Thus, palatal constraints  
48  
49  
50  
51 are not obligatory.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 In our experience, the best metric was the Normalized Averaged Largest Curvatures  
5  
6  
7 (NALC). Both NALC and NALCi included a normalization factor, which allowed them to  
8  
9  
10 distinguish between the two /s/ types and also show the relationship between tongue  
11  
12  
13 shape and palate angle. However, NALC is more convenient and cost effective than  
14  
15  
16 NALCi because it does not require interpolation of additional points, The NALC  
17  
18  
19 prevented tongue size differences from affecting curvature values and obscuring subject  
20  
21  
22 differences.

TABLE 1. Median values of curvature in Apical and Laminal groups.

	Apical	Laminal	$p$ -value
MC	$-0.020 \pm 0.02$	$-0.010 \pm 0.02$	0.090
ALC	$0.062 \pm 0.02$	$0.057 \pm 0.01$	0.589
NALC	$0.225 \pm 0.10$	$0.368 \pm 0.14$	0.028*
NALCi	$0.158 \pm 0.07$	$0.260 \pm 0.10$	0.028*

## FIGURE CAPTIONS

Figure 1. Mid-sagittal MRI images of apical (left) and laminal (right) /s/.

Figure 2. Twenty midline tongue profiles showing apical and laminal shapes.

Figure 3. Measurement points selected on (a) the palate cast, (b) the midsagittal palate profile, and (c) the tongue surface. Palate points are (1) the interdental papilla between incisors, (2) the base of the incisive papilla, (3) the deepest point of the palate adjacent to the first molars. The eight tongue points include 2 landmarks: (1) the tongue tip, (5) the anterior edge of the first molars. Tongue points are equidistant.

Figure 4 Curvature calculation and sign assignment in discrete points. The global circle (dotted line) fit to all eight points, has a radius  $R$  and is centered at  $C$ . Local curvature values are extracted by fitting a circle on 3 neighboring points. The local circle has a radius  $r$  and is centered at  $c$ . The global fit is used to determine the sign of the local

1  
2  
3 curvature values. A negative sign is assigned when the internal angle in the segment  
4  
5  
6  
7 cpC is larger than  $90^\circ$  (blue), and positive if the angle is smaller than  $90^\circ$  (red).

13

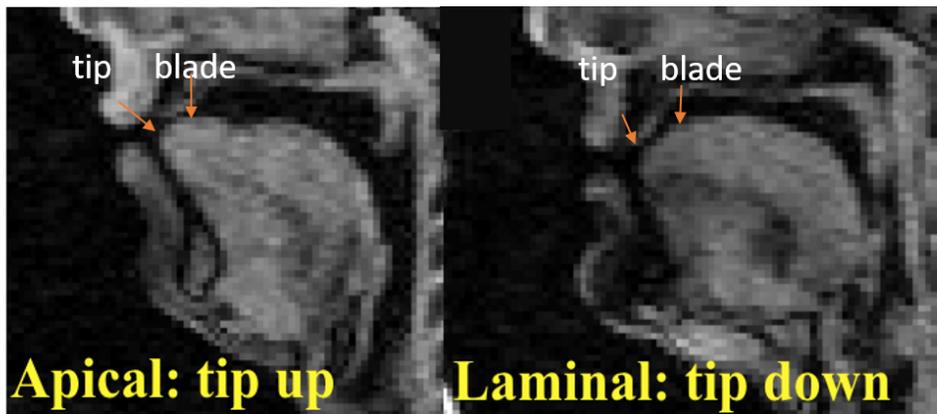

14  
15 Top row: the minimum curvature method (MC) places emphasis on curvatures with  
16  
17  
18 relatively large negative values (left), and values close to zero (right). Second row: the  
19  
20  
21 average largest curvature method (ALC) averages the 2 largest curvature values  
22  
23  
24 (dotted, solid) in the tongue profile. Smaller circles yield larger averaged curvature  
25  
26  
27 values and typically reflect apical shapes (left). Third row: the normalized ALC method  
28  
29  
30 (NALC) is the ratio of the ALC divided by the global curvature (aqua), which normalizes  
31  
32  
33 for size differences among subjects. Laminal tongue profiles have ratios closer to 1  
34  
35  
36  
37  
38  
39 (right). Bottom row: the NALC with interpolated points method (NALCi) is applied to a  
40  
41  
42  
43 more continuous (interpolated) curve to assess the effects of closer points. Note that in

Mid-sagittal MRI images of apical (left) and laminal (right) /s/.

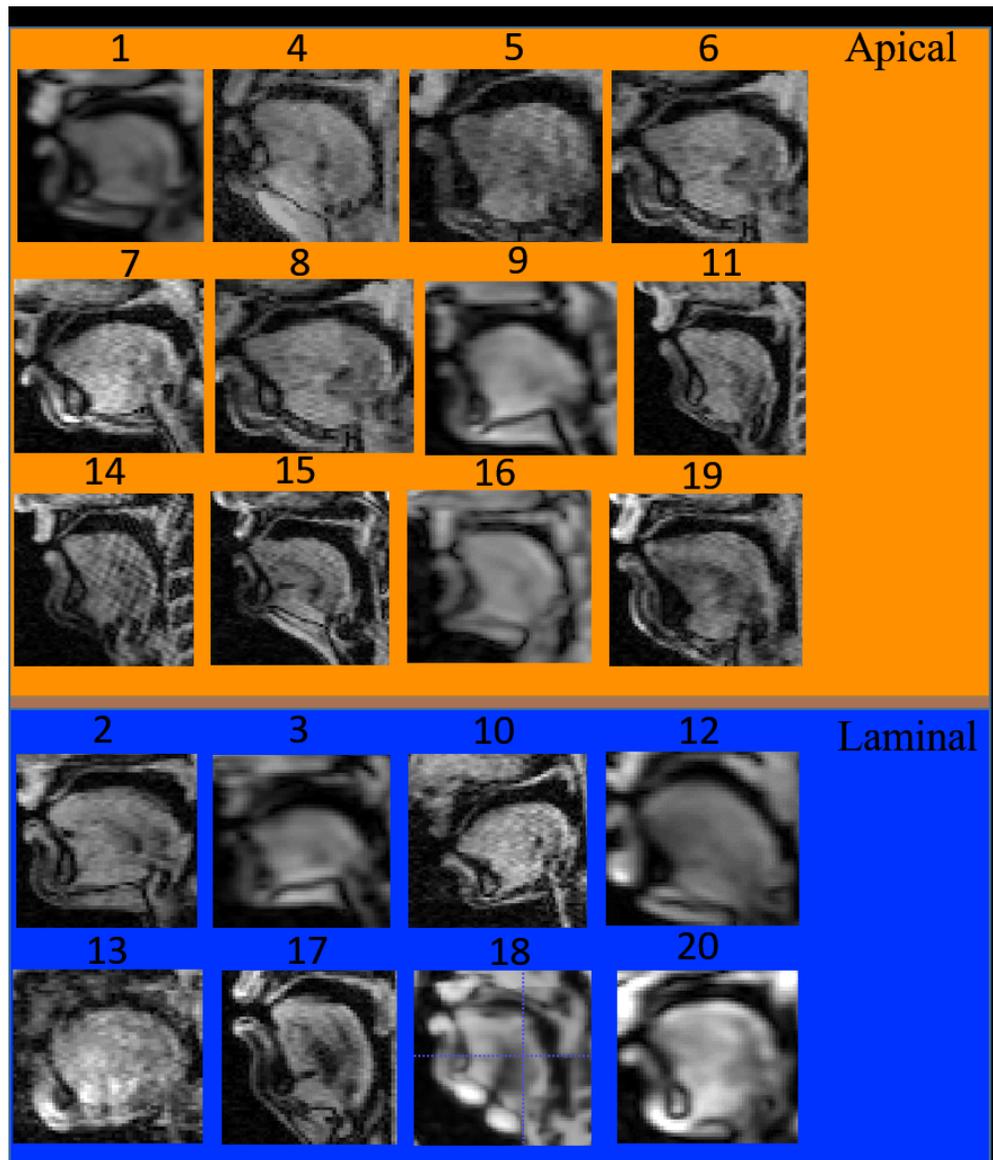

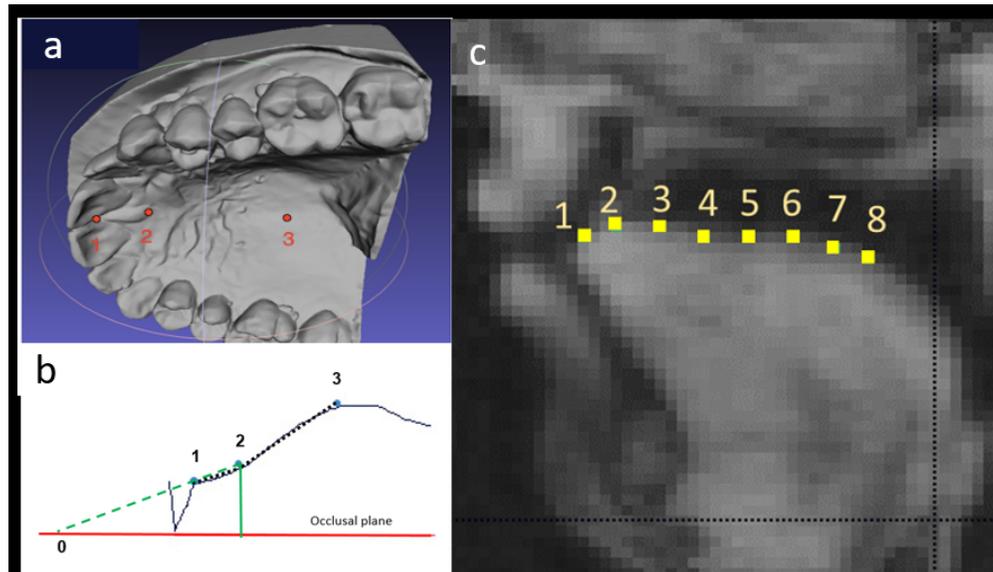

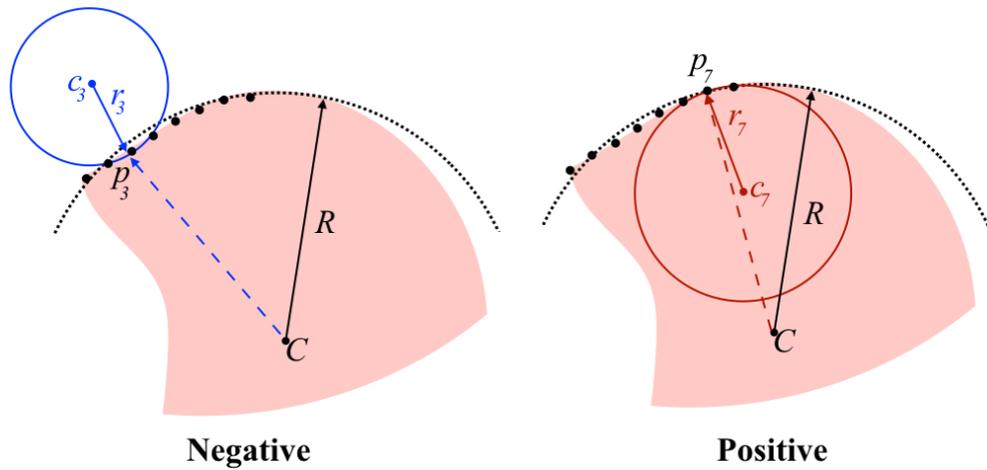

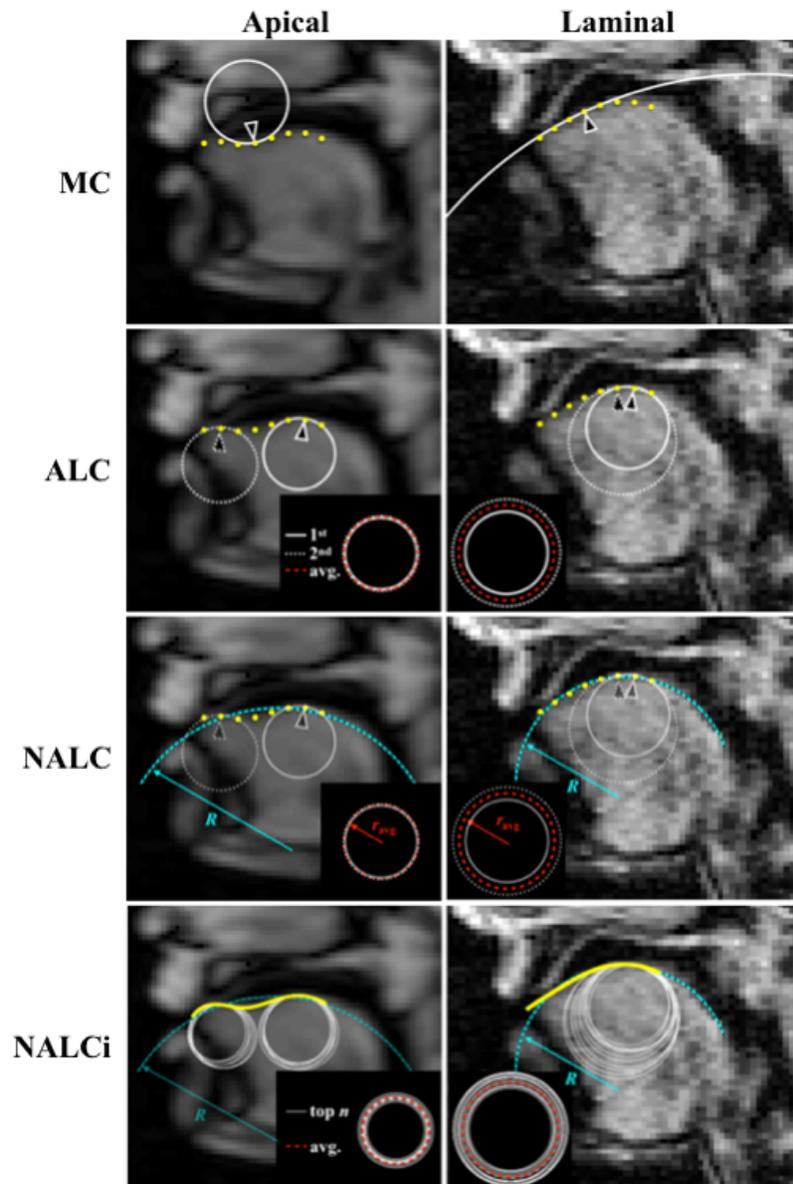

Figure 2. Twenty midline tongue profiles showing apical and laminal shapes.

Measurement points selected on (a) the palate cast, (b) the midsagittal palate profile, and (c) the tongue surface. Palate points are (1) the interdental papilla between incisors, (2) the base of the incisive papilla, (3) the deepest point of the palate adjacent to the first molars. The eight tongue points include 2 landmarks: (1) the tongue tip, (5) the anterior edge of the first molars. Tongue points are equidistant.

Curvature calculation and sign assignment in discrete points. The global circle (dotted line) fit to all eight points, has a radius  $R$  and is centered at  $C$ . Local curvature values are extracted by fitting a circle on 3 neighboring points. The local circle has a radius  $r$  and is centered at  $c$ . The global fit is used to determine the sign of the local curvature values. A negative sign is assigned when the internal angle in the segment  $cpC$  is larger than  $90^\circ$  (blue), and positive if the angle is smaller than  $90^\circ$  (red).

Strategies for numerical distinction between apical and laminal profile shapes. Top row: the minimum curvature method (MC) places emphasis on curvatures with relatively large negative values (left), and values close to zero (right). Second row: the average largest curvature method (ALC) averages the 2 largest curvature values (dotted, solid) in the tongue profile. Smaller circles yield larger averaged curvature values and typically reflect apical shapes (left). Third row: the normalized ALC method (NALC) is the ratio of the ALC divided by the global curvature (aqua), which normalizes for size differences among subjects.

Laminar tongue profiles have ratios closer to 1 (right). Bottom row: the NALC with interpolated points method (NALCi) is applied to a more continuous (interpolated) curve to assess the effects of closer points. Note that in NALCi, the interpolated points are close together and give the impression of a continuous line.

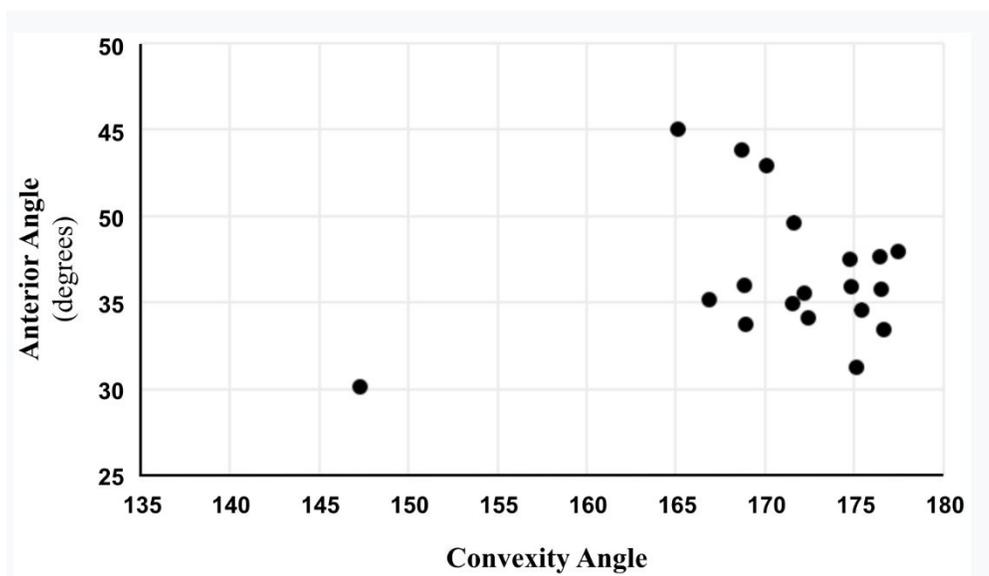

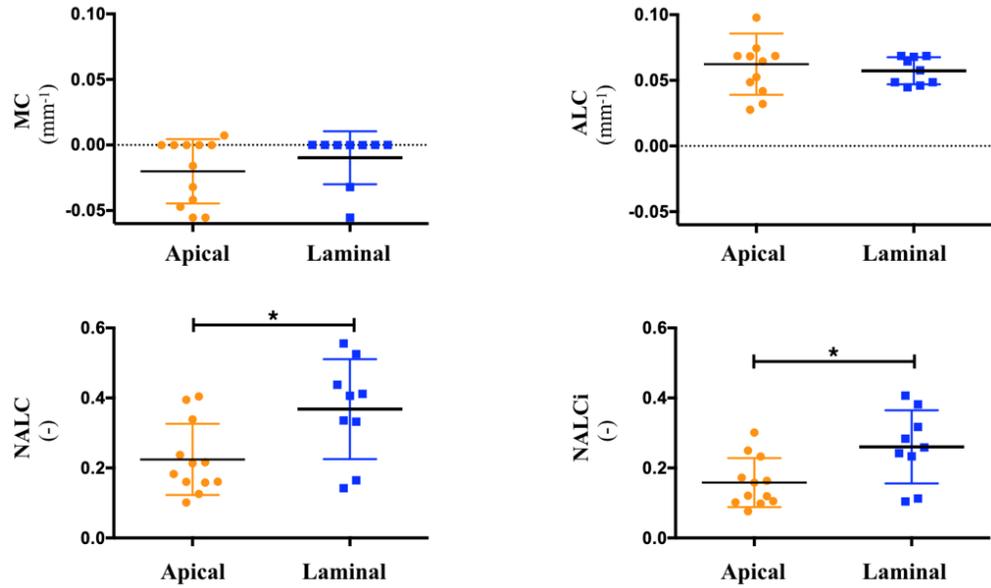

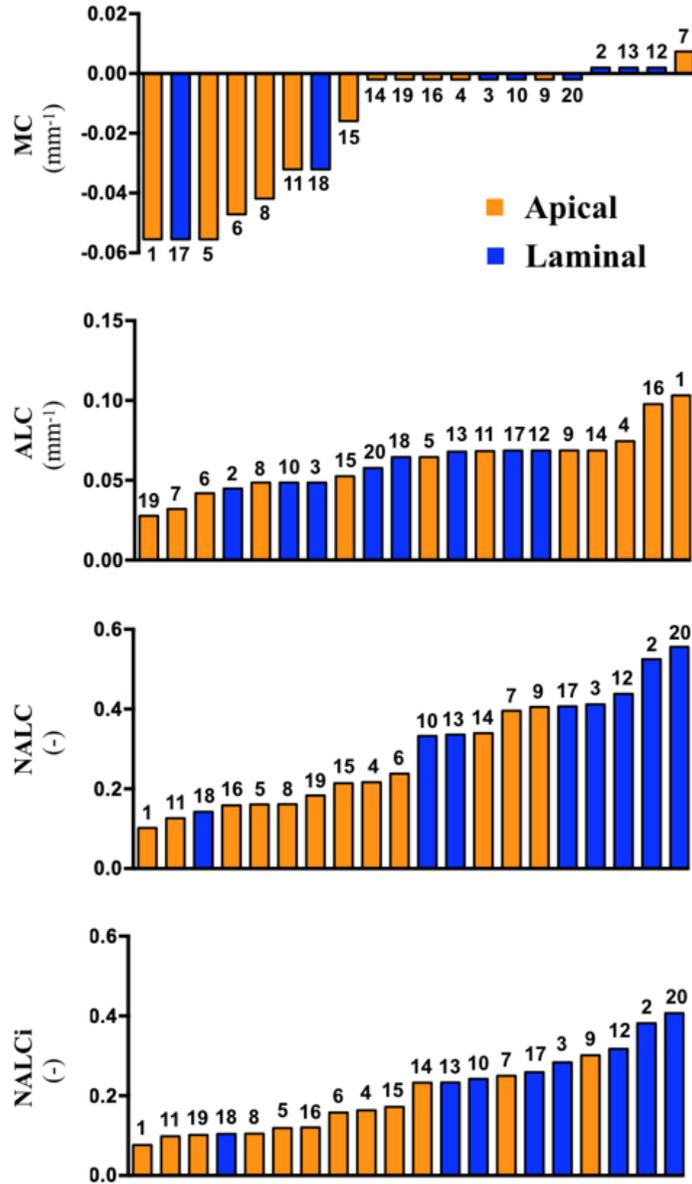

Figure 6. Scatterplot of the Convexity Angle and the Anterior Angle of the Palate.

Group comparison per different shape classification metrics. MSC and ALC are curvature measurements with units as noted, NALC and NALCi are both normalized curvature radii ratios (the mark (-) denotes a dimensionless quantity). Significance is indicated with an asterisk, which indicates p<0.05.

Ranked shape classification metrics. The metric value for each participant was ranked in ascending order along the x-axis.

Points for curvature calculation
